

CONVEX

Portfolio Manager

How I record trades, translate option legs into portfolio risk, and use a rules-based framework to manage exposure.

Illustrative view from the synthetic production-style workbook. The screenshots in this guide are examples, not a live account.

DOCUMENT SCOPE

A working guide to the model architecture, daily workflow, major calculations and decision rules. The associated public Excel workbook and displayed performance figures use fictional demonstration data. This document describes the model; it is not an independent validation of its formulas or trading results.

INSIDE / Trade journal • Greek exposure • ACTION rules • Risk limits • Volatility • Scenarios

PATRICK • SELF-DIRECTED PORTFOLIO RESEARCH

September 2026 / Portfolio project documentation

FIELD GUIDE / 01

The problem I set out to solve

A trade journal tells me what I own. It does not, by itself, tell me what the portfolio is exposed to. CONVEX closes that gap by connecting the trade record, options risk, position-management rules and portfolio limits in one workbook.

The operating idea

I start with a trade that makes sense at the strategy level: a LEAP, a debit spread, a put-credit spread, a short call overlay or a hedge. The important question is what happens once I combine that trade with everything already in the book. Direction, convexity, time decay and volatility do not disappear simply because the position is labelled as a strategy.

The calculation chain

Stage	Job	Worksheet
01 Record	Store trade identity, structure, price, dates and status.	Options_Journal
02 Select	Build the active position set and classify each trade.	Positional_Analysis
03 Decompose	Create signed option legs and attach option data.	Risk_View
04 Rebuild	Aggregate leg values and Greeks at position level.	Positional_Analysis
05 Assess	Apply limits, factor exposure, scenarios and sizing.	Risk_Manager_v2
06 Decide	Translate measurements into levels and action labels.	ACTION / SELL SIGNAL

THE KEY DEPENDENCY

Positional_Analysis sends position identities and structures into Risk_View. Risk_View returns leg-level prices and Greeks for use in position analytics. The sheets depend on each other at the sheet level; that is not, by itself, proof of a circular cell reference.

Supporting sheets

DATA_1 supplies price-history statistics; Event_Dashboard supplies catalysts; STATE_SNAPSHOT stores prior trend, volatility state and trailing-floor levels; Scenario_Lab runs one-trade what-if analysis. The private workbook uses Microsoft market data and Options Samurai. The public demonstration substitutes synthetic inputs where appropriate.

FIELD GUIDE / 02

My operating routine

The dashboard is not the first step. The first step is making sure the inputs and position list describe what I actually hold.

When	What I do	What I check
Before review	Refresh available data and confirm account inputs.	Spot, option prices, Greeks, equity, BP and dated state snapshot.
After execution	Add or update a trade in the journal.	Unique ID, signed premium, structure syntax, expiry, quantity, factor.
Position pass	Open Positional_Analysis and scan DTE order.	Unpriced names, STOP/FLOOR/CAP, ACTION and SELL SIGNAL.
Risk pass	Read Risk_View and Risk_Manager_v2.	Leg signs, beta-adjusted dollar delta, Greeks, factor and limits.
Before adjustment	Use the cut list, sizing checker and Scenario_Lab.	Size of adjustment; price/time/IV sensitivity; event proximity.
End of review	Record any close, roll or resize; refresh the snapshot intentionally.	Journal status and prior-state values remain coherent.

A new trade goes through the same sequence

I enter the trade once in Options_Journal. The active-book filter includes rows marked **OPEN**, then the position sheet normalizes the trade into a play type. Risk_View parses the ticket into option legs. Position-level analytics sum the legs and attach the relevant market, volatility and management data. The Risk Manager shows what that position contributes to the whole book.

EXAMPLE: A CREDIT SPREAD

A put-credit spread is stored as one strategy in the journal but appears as one short put leg and one long put leg in Risk_View. A purchased protective put must carry a positive signed contract quantity; the net delta of a correctly constructed protective put is normally negative. I review the signs before trusting the rolled-up number.

A useful rule for the entire workbook

No populated cell is automatically a reliable input. A blank vendor value, expired quote, outdated buying-power figure or stale state snapshot can produce a plausible-looking output. The data-quality indicators are therefore part of the review, not decoration.

FIELD GUIDE / 03

The journal is the system of record

The journal stores one row per trade. It also supplies the trade ID that links the strategy to the active-position and leg tables.

	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	V	W	AB

Figure 1. Synthetic journal: trade IDs, strategy, status, structure, expiration and quantity. The screenshot is cropped to the input and identity area.

Fields I enter

Identity and timing	Economics and classification
Trade ID; strategy; setup; OPEN/CLOSED; position; ticker.	Structure; strike ticket; entry/expiry; contracts; signed net entry price.
Breakeven sign and level; optional max loss.	Commissions; exit date, quantity and price; factor; notes.

Two conventions matter

- **Status:** changing a row from OPEN to CLOSED removes it from the live book. An incorrect status can make exposure disappear from every downstream summary.
- **Premium:** the original journal uses a signed per-contract net entry price: debit paid is negative; credit received is positive. The leg builder derives buy/sell side from the strategy-specific structure and premium convention, not from a bullish/bearish label alone.

$$\text{Entry premium (\$)} = \text{contracts} \times \text{signed entry price} \times 100$$

This assumes standard 100-share equity-option multipliers. Nonstandard contracts require an explicit multiplier.

How I use it in practice

I record the trade after execution and confirm that its identifier is unique and the strike ticket follows the workbook's accepted syntax. I then verify that the trade appears in Positional_Analysis and that the number of legs in Risk_View matches the actual structure. After partial or full exits, I update exit quantity and status instead of relying on the dashboard to infer a fill.

FIELD GUIDE / 04

Decompose before aggregating

The journal sees strategies. Risk_View must see individual contracts. This is where an apparently simple spread becomes a measurable collection of long and short exposures.

Trade ID	Ticker	Structure	DT	Option Type	Leg Side	Strike	Contract Qty	Signed Qty	Current Contract Price	Delta	Theta	Vega	Gamma	Net Delta	Net Theta	Beta Adj	Net Delta

Figure 2. Signed-leg table from the synthetic workbook, showing option type, strike, quantity, raw Greeks and derived leg exposures.

The leg mathematics

$\text{signed_qty} = +\text{contracts (long) or -contracts (short)}$

$\text{net_delta (shares)} = \text{leg_delta} \times \text{signed_qty} \times 100$

$\text{net_theta (\$/day)} = \text{leg_theta} \times \text{signed_qty} \times 100$

$\text{dollar_delta} = \text{net_delta (shares)} \times \text{underlying_spot}$

$\text{beta_adj_dollar_delta} = \text{dollar_delta} \times \text{beta_vs_SPY}$

What the two delta views answer

Dollar delta estimates first-order P&L for a percentage move in **that underlying**. Beta-adjusted dollar delta translates the directional component into an approximate SPY-equivalent exposure using estimated beta. I use the latter as a common reference when considering an index hedge, but beta is an estimate: it can change sharply, especially during market stress.

DATA QUALITY BEFORE PRECISION

A position with missing spot, price, expiry or Greek data cannot be represented by a clean risk number. The priced/unpriced count and Needs_Review fields are controls; they are not a replacement for reconciling with the brokerage position record.

FIELD GUIDE / 05

From a position to a decision

Positional_Analysis is my working screen. It collects price, delta, volatility, time to expiry, trend and management levels so that I can review positions consistently rather than improvising a different rule each day.

Figure 4. Decision-facing fields: IV/VRP/skew, theta, net dollar delta, management level and ACTION.

The fields I scan first

Field	Purpose
PLAY / DR-CR	Classifies structure and whether premium was paid or received.
DTE / P&L; / Premium held	Shows clock, position economics and share of the book.
IV, VRP, RVOL and trend	Describes the volatility and price context.
STOP / FLOOR / CAP	Defines the current position-management reference level.
ACTION and SELL SIGNAL	Applies ordered rules; the result is a review prompt, not an order.

The signal is deliberately auditable

ACTION runs through a sequence of rules, taking the first applicable outcome. That distinction matters: a position that has hit a stop cannot be reclassified as an attractive premium-selling opportunity merely because implied volatility is high.

FIELD GUIDE / 06

The management rules

This is the current rule design described in the technical handoff, not a set of statistically validated trading outcomes. Thresholds are configurable research assumptions.

Priority	Condition, in brief	Output
0	Salvage ratio below 0.20.	CLOSE ONLY
1	Stop, trailing floor or cap reached; selected trend/DTE exit conditions.	CLOSE
2	LEAP inside 90 days to expiry, if no higher rule fired.	ROLL
3	Approaching floor, worsening trend, debit down 35%, or LEAP at 112 DTE.	WARNING
4	Rich/extreme vol, low extrinsic share and SELL SIGNAL approved.	OVERLAY
5	Event inside 10 days, profit without floor, or intermediate time/vol triggers.	CAUTION
6	No earlier condition applies.	OK

Position levels

```
debit STOP = 0.50 x abs(entry premium)
```

```
credit CAP = 0.25 x abs(entry premium)
```

```
trailing FLOOR = max(prior_floor, new_ATR_based_floor)
```

A floor activates only once the position has gained at least 25% (40% for LEAP-class positions), according to the handoff. The ATR multiplier varies by trend and volatility state: a wider floor in favorable regimes, tighter in adverse conditions. The snapshot is essential: without a saved prior value, a trailing floor is not actually persistent.

Overlay eligibility

The SELL SIGNAL requires a LEAP, sufficiently high book-relative VRP rank (at least 0.70), a non-bearish trend, no matching event in 45 days and a qualifying volatility state. A short call overlay changes upside and assignment/exercise exposure. The label is a screening result, not proof that the overlay is profitable.

FIELD GUIDE / 07

When the book needs to shrink

Portfolio limits describe the amount of risk that needs to change. The cut list translates that requirement into a list of specific positions for review.

$$\text{CUT_SCORE} = \text{premium_held} \times (1 - \text{POP}) \times (1 + \text{factor_share})$$

The model combines three inputs: amount of premium currently committed, estimated chance of not finishing profitably, and concentration in the tagged theme. It then ranks the positions and accumulates premium through the ordered list. Tagged hedges are excluded by design.

How I interpret the ranking

Input	Reading	Important caveat
Premium held	Larger exposure adds more weight.	Premium is not the same as true maximum loss or broker margin.
1 - POP	Lower estimated POP raises the score.	POP is model-dependent; it is not a realized loss probability.
1 + factor share	Crowded themes receive an added penalty.	Factor tags are manually assigned, not statistical factors.

WHAT IT IS - AND WHAT IT IS NOT

CUT SCORE is a triage heuristic, not an optimization that maximizes expected return or guarantees the least-cost liquidation path. A high rank prompts review of liquidity, spread width, hedging role, taxes, assignment risk and execution cost before I act.

Why a separate hedge line matters

Risk_Manager_v2 reports hedge exposure separately and includes a total excluding hedges. I can see whether the directional book is concentrated before allowing protection to offset it in the headline totals. A net number alone can obscure the size of offsetting positions.

Read the portfolio from the top down

My first portfolio question is whether the inputs are complete. The second is which limit is binding. Only then do I ask where I can change exposure.

Figure 5. Synthetic Risk Manager: status, pricing coverage, account basis, delta and risk meter.

A limit is more useful than a color

Each monitored dimension has a current reading, warning level, breach level, remaining headroom, status and percentage of limit. The overall status escalates when a warning or breach is present. The binding-constraint field points to the dimension requiring attention; the weighted risk meter is an additional summary, not a substitute for the limit table.

Figure 6. Risk limits, drivers, factor concentration charts and simplified SPY × IV stress surface.

CHECK THE DENOMINATOR

Ratios to equity are only comparable if all panels reference the same equity and buying-power inputs. In development, mismatched account inputs and beta lookups produced misleading readings. The public presentation should not be treated as independently reconciled until the downloadable file passes a workbook-level validation.

FIELD GUIDE / 09

Exposure should respond to volatility

The workbook uses two separate controls: one for the amount of option premium to hold given realized volatility, and another for buying-power utilization given the SPY implied-volatility regime.

1 / Premium scaling

```
scale = desired_portfolio_RVOL / current_portfolio_RVOL
```

```
target_premium = current_premium x scale
```

```
premium_adjustment = target_premium - current_premium
```

For example, the synthetic snapshot displays about 33.5% current RVOL against a 20% desired value. The ratio is roughly 0.60. In that panel the indicated premium declines from approximately \$15.3k to \$9.1k. This is a proportional sizing heuristic; premium is not a complete measure of portfolio risk.

2 / Volatility-regime utilization

```
target_util = clamp(base_util x (IV_anchor / SPY_IV)^k, floor, cap)
```

As benchmark IV rises above the anchor, the target utilization falls when k is positive. A separate current-versus-target comparison generates a risk gap and suggested buying-power adjustment. It is essential that the current utilization use the same account inputs as the main Risk Manager.

Figure 7. Vol-target premium scaler and sensitivity grid. Figures shown are snapshots of fictional inputs.

A practical limit

Inverse-volatility weights and a single volatility ratio do not constitute a full portfolio-risk model. Correlations, option nonlinearities, jump risk and liquidity may change in a drawdown. I treat the output as a sizing reference alongside the other limits, not as an automatic instruction.

FIELD GUIDE / 10

What changes if price, time and IV move together?

Scenario_Lab lets me select one open trade and look beyond the local Greek approximation. I choose a price shock, a number of calendar days forward and an implied-volatility shift.

Figure 8. Synthetic scenario: a selected long call, input shocks and model-implied P&L.; Not an actual trade result.

What the calculation does

Each option leg is repriced under the new spot, reduced time to expiry and shifted IV, using the workbook's Black-Scholes implementation. Leg scenario values are combined using signed quantities and the contract multiplier. The report compares the new value with the current mark and the original entry cost.

```
scenario_PnL = sum(leg_qty_signed x 100 x (new_price - old_price))
```

FIELD GUIDE / 10

Scenario sensitivity | continued

The highlighted cell belongs to the selected combination of price, time and implied volatility assumptions; neighbouring cells reveal how sensitive that conclusion is to the chosen shock.

0,000

Figure 9. The two sensitivities vary spot move against IV shift or elapsed days. The highlighted cell corresponds to the chosen scenario.

SCENARIOS ARE NOT FORECASTS

Black-Scholes assumes a simplified volatility process and European exercise. Many U.S. equity options are American-style and dividend/early-exercise effects can matter. The grid also assumes the entered volatility shocks, not a full evolving skew surface.

FIELD GUIDE / 11

Events and the feedback loop

Events are only useful when they alter the way a position is evaluated. The calendar includes manually entered catalysts and recurring events, and its proximity tests feed the position-management layer.

IMPORTANT EVENTS - FILTERED VIEW (adjust filters below)

Figure 10. Event calendar captured in September 2026. Dates are illustrative historical screenshots, not an up-to-date economic calendar.

How event proximity is used

The handoff describes a 10-day window feeding CAUTION and a 45-day window blocking LEAP call-overlay eligibility. The original matching approach looks for the ticker inside the event name, so missing symbols or inconsistent naming can silently prevent a match. A dedicated symbol field would be more reliable.

FIELD GUIDE / 12

Performance is a separate question

I look at closed trades by strategy, structure, entry and exit DTE, and time utilized. This helps me frame better questions about execution and holding periods; it does not prove the trading rules work.

Historical Trade Analytics						
Performance deep-dive across 139 closed trades Options Journal						
Executive Summary						
Total P&L		Win Rate		Profit Factor		Avg Win
\$5,919.92		56.8%		1.57		\$207.04
Wins		Losses		Max Win Streak		Max Loss Streak
79		60		11		6
Strategy Performance						
Strategy	Trades	Total P&L	Avg P&L	Win Rate	Avg Days Held	% of Total P&L
Macro	16	\$4,210	\$263	87.5%	24.6	71.1%
MR	23	\$2,806	\$122	73.9%	23.4	47.4%
Tech	26	\$2,035	\$78	50.0%	30.3	34.4%
Consolidation	4	\$254	\$64	75.0%	20.3	4.3%
Leap	1	\$222	\$222	100.0%	49.0	3.8%
Income	1	\$213	\$213	100.0%	16.0	3.6%
Rolled	3	(\$39)	(\$13)	33.3%	72.0	-0.7%
Trend	30	(\$93)	(\$3)	56.7%	35.7	-1.6%
Spec	3	(\$128)	(\$43)	66.7%	48.0	-2.2%

Consolidated

Figure 11. Synthetic historical-performance dashboard. The displayed results are fictional and the legacy chart is not evidence of an independently reconciled trade history.

The figures are descriptive

$$\text{win_rate} = \text{winning_closed_trades} / \text{all_closed_trades}$$

$$\text{profit_factor} = \text{gross_winning_PnL} / \text{abs}(\text{gross_losing_PnL})$$

$$\text{expectancy_per_trade} = \text{win_rate} \times \text{avg_win} + \text{loss_rate} \times \text{avg_loss}$$

I separate open positions from the closed-trade record and avoid presenting a static chart as current account performance. The supplied handoff identified a historical dashboard whose pasted figures differed from the journal. Before any quantitative conclusions, I would rebuild its aggregates from a synthetic, internally consistent trade ledger and check commissions, partial exits, strategy classification and overlapping positions.

DO NOT READ THIS AS TRACK RECORD

Every displayed result in the public workbook is fictional. Neither the screenshots nor the worksheet demonstrate verified realized returns, trading skill, model edge or live performance.

FIELD GUIDE / 13

Calculation reference

These are the principal relationships behind the guide. Labels and units are spelled out because exposure errors are often unit errors.

Measure	Definition / interpretation
Signed leg quantity	+ contracts for long; - contracts for short.
Dollar delta	Leg delta $\times$ signed contracts $\times$ 100 $\times$ underlying price; first-order P&L; for a 100% proportional underlying move.
Delta P&L; , small move	Approximately dollar delta $\times$ underlying return (decimal).
Beta-adjusted dollar delta	Dollar delta $\times$ estimated SPY beta; approximate benchmark-equivalent sensitivity.
Theta / day	Sum of leg theta $\times$ signed contracts $\times$ 100, provided source theta is quoted per share per day.
Vega / IV point	Sum of source vega $\times$ signed contracts $\times$ 100 if source vega is per share per one IV point. Confirm vendor convention.
Gamma P&L; / 1% spot move	Approximately $\frac{1}{2} \times$ leg gamma $\times$ signed contracts $\times$ 100 $\times$ $(0.01 \times \text{spot})^2$. This is the quadratic term, not a full scenario.
POP model	A lognormal terminal-price approximation using spot, breakeven, implied vol and remaining time; not an empirical win rate.
Cut score	Premium held $\times$ $(1 - \text{POP}) \times (1 + \text{factor share})$.
Vol premium scale	Desired RVOL / current RVOL; target = current premium $\times$ scale.
Regime target utilization	Clamped base $\times$ (anchor IV / current benchmark IV) ^k .
First-order stress	Approx. beta-adjusted dollar delta $\times$ SPY return + portfolio vega $\times$ IV-point shock; gamma omitted from grid.

UNIT CHECK

A \$10,000 dollar-delta position has about \$100 first-order P&L; for a 1% move in its own underlying, assuming delta is locally stable. For a hedge against SPY, use the appropriately beta-adjusted exposure, not the sum of raw share deltas from different stocks.

FIELD GUIDE / 14

Use the model with its limitations visible

The point of documentation is not to make a spreadsheet appear infallible. It is to show which inputs I control, what the calculations approximate and where a reviewer should test before relying on the output.

Area	Known boundary
Market data	Private implementation depends on Microsoft price data and Options Samurai. Public examples are synthetic; vendor redistribution permissions require separate review.
Data quality	Missing prices, stale snapshots and lookup errors can conceal exposure. Priced/unpriced indicators must be reviewed.
Capacity	The original active position grid and leg table used fixed display capacities; an overflow could omit positions.
Model assumptions	POP is lognormal; Greeks are local; stress grid is first-order; beta may fail in regime changes.
Rules and limits	Several thresholds are judgmental and some limits were flagged uncalibrated. No backtest validation is claimed.
Performance	Screenshots and public results are fictional. A legacy performance chart was static rather than a verified journal-linked analysis.
Trade decisions	ACTION, overlay and cut ranks are review prompts. No execution, fills, taxes or slippage are guaranteed.

How to explore the downloadable demo

- Open **Options Journal**; review the fictional trade records and identify a spread and a LEAP.
- Find the trade in **Positional Analysis**; note DTE, premium, dollar delta, LEVEL and ACTION.
- Open **Risk View**; reconcile the number of legs, the signs and the summed Greeks.
- Read **Risk Manager_v2**; compare exposure, factor tags, limits and volatility-targeting outputs.
- Pick the same trade in **Scenario Lab**; change spot, days and IV, then compare P&L surfaces.
- Check **Event Dashboard**; observe that the example dates are snapshots rather than current releases.

Document basis

Prepared from the author-supplied technical handoff and synthetic workbook screenshots. The explanation describes design intent and representative formulas; it is not a cell-by-cell audit, proof of broker reconciliation, verification of licensed market-data rights or evidence of historical trading performance. For a production release, reconcile the downloadable workbook directly against its journal, data feeds and actual Excel recalculation.
